Abstract

The nanosized precursors of yttria-stabilized zirconia (YSZ) were prepared via a water/CTAB/hexanol reverse microemulsion. The surface hydroxyl groups of the YSZ precursor were substituted by siloxyl groups using HMDS (hexamethyldisilazane) as starting material. The untreated and treated YSZ powder were characterized by ultraviolet–visible–near-infrared spectrometer, FT-IR spectrometer, X-ray diffractometer, BET surface-area analyzer, and electron probe microanalysis (EPMA). After HMDS treatment, the amount of Si atom grafted on the nanoparticle surface was about 1 mol%. The crystallite size of the treated powder was smaller and the surface area was larger than the untreated powder. © 2006 Elsevier B.V. All rights reserved.

1. Introduction

Zirconia powder is useful in many advanced structural, high-temperature and electrical ceramic applications. Zirconia has three crystalline phases including cubic, tetragonal, and monoclinic. Among these structures, the monoclinic phase is a thermodynamically stable structure at low temperature. The tetragonal phase of zirconia, however, is of great interest because of its application [1–3]. The doping with Mg²⁺, Ca²⁺, and Y³⁺ could stabilize tetragonal zirconia at a low temperature. For example, the yttria-stabilized zirconia (YSZ) has been widely used in oxygen sensors. Numerous techniques have been applied to produce pure or stabilizing additive doped zirconia nanocrystalline, including sol-gel [4], hydrothermal [5], and precipitation processing [6]. The precipitation technique is a convenient, safe, and inexpensive process, but it produces particles with a wider size distribution and irregular particle shape that reduce the quality of ceramics. It seems to us that these problems can be overcome by the reverse microemulsion precipitation technique. Reverse microemulsion solution is a transparent, isotropic and stable system with nanosized droplets dispersed in a continuous oil phase.

The water droplets can be treated as nanosized reactors for the formation of nanoparticles [7]. Recently, the nanoparticles of zirconia precursor were successfully synthesized via a reverse microemulsion route [8–11].

To achieve fully crystalline nanocrystals of zirconia, a further calcination process is necessary. However, the crystal sizes of YSZ nanoparticles are sensitive to a firing process that would increase the crystal size at an elevating temperature or with a prolonged heat treatment. Hence, special attention should be paid to the control of crystal size and crystal structure during calcination. In the literature HMDS (hexamethyldisilazane) has been utilized to inhibit crystal growth. It can replace hydroxyl groups to form noncondensing methyl siloxyl surface groups, and they decompose in air at 350 °C to produce SiO₂ particles that serve as the “pinning” particles for the inhibition of crystal growth [12]. The aim of this work is to compare the properties of two kinds of YSZ powder prepared via a reverse microemulsion process without and with a post treatment using HMDS.

2. Experimental

In this experiment, all the raw materials were used as received. Zirconyl nitrate, yttrium nitrate, surfactant CTAB (Cetytrimethyl ammonium bromide), and HMDS (hexamethyldisilazane) were

purchased from Aldrich and aqueous ammonia solution (28 wt.%) and 1-Hexanol (98.9%) were from Nacalai Tesque and TEDIA, respectively.

For comparison two kinds of YSZ powder were prepared, i.e., with and without HMDS treatment. The procedures for the two types of powder were the same until the hydrous YSZ was produced. The first step was to prepare a reverse microemulsion by mixing a certain amount of hexanol, surfactant, and aqueous solution of yttrium and zirconyl nitrate in a 500 ml jacket reactor. Then this reverse microemulsion with the mole ratio of $0.06 \text{ Y}^{3+}/0.94 \text{ Zr}^{4+}$ was added dropwise into the reverse microemulsion of ammonia water with vigorous magnetic-stirring to obtain a slurry of YSZ precursor. The YSZ precursor was separated from the oil phase by centrifugation and further washed with water, ethanol (99.5%), respectively, and dried at 80 °C over 12 h. At this stage, the product was referred to as hydrous YSZ powder. Then the hydrous YSZ powder was subjected to the HMDS treatment and was further calcined at various temperatures for 1 h to obtain the

fully crystalline YSZ nanocrystals. The HMDS treatment of hydrous YSZ powder was conducted at 150 °C for 1 h in a vacuum vessel, following the procedures used by Wu et al. [12].

The particle size and morphology of the resultant YSZ nanoparticles were examined by a transmission electron microscope (TEM, Hitachi-7100). The crystal structure of the product powder was determined by an X-ray diffractometer (Mac Science, MXP-3 TXT-7266). The mean zirconia crystallite size was calculated from the Debye–Scherrer equation based on the full width at half maximum intensity of the $t_{(101)}$ peak for $t\text{-ZrO}_2$. The specific surface area (BET) of the samples was determined from physical adsorption of N₂ at $T=78 \text{ K}$, measured in a Micromeritics ASAP 2010 analyzer. Ultraviolet–visible–near-infrared (UV–VIS–NIR) spectra were obtained at room temperature, measured by a Hitachi model U3410 spectrometer. Chemical bonding and functional groups were investigated with a Fourier transform infrared spectroscopy (FT-IR, Bio-Rad model FTS-40) and the FT-IR spectrum was collected after 16 scans with a normal resolution of 4 cm^{-1} . The weight loss and reaction evolution of the powder were determined with a thermal analyzer (TGD-7000RH, Ulvac/

Riko). The samples were heated from 25 °C to 1000 °C with a heating rate of 10 °C/min in a static air atmosphere.

3. Results and discussion

3.1. Particle characterization

A stable reverse microemulsion of water/CTAB/hexanol system can exist in a certain area on the three-component phase diagram as reported by Lufimpadio et al. [13]. In this experiment 0.25 M ZrO(NO₃)₂ and 6 N NH₄OH aqueous solution instead of pure water were used. The stable region of our system was slightly narrower than that of pure water. Then the two stable solutions of reverse microemulsion were mixed to form particles. The TEM micrograph of the YSZ precursors produced is shown in Fig. 1. The precursor nanoparticles, which had a spherical morphology and a particle size range of 10–15 nm, were dispersed in CTAB matrix.

To detect the possible substitution of hydroxyl groups by the methyl siloxyl groups on the YSZ precursor before and after HMDS treatment, the samples were first examined by an ultraviolet–visible–near-infrared spectra analyzer. The –OH groups had strong absorption in the bands at 1180, 1390, and 1720 nm for the untreated samples [12]. After HMDS treatment, the –OH absorption intensities at those bands were reduced. The samples were further subjected to FT-IR spectra analysis. Fig. 2 shows the FT-IR spectra of untreated and HMDS treated YSZ powder calcined at 650 °C. The band at 1087 cm⁻¹ on curve (b) indicated the formation of Zr–O–Si bond in the HMDS treated sample [14,15]. We concluded that some of the –OH bonds on the precursor were replaced by the O–Si bonds after HMDS treatment.

3.2. TG/DTA analysis

To obtain fully crystalline nanoparticles of YSZ, the microemulsion-derived YSZ precursors need further calcination at higher temperatures. Calcination of the precursor particles burned out residual surfactant and nitrate group, and then the precursor particles transformed into tetragonal phase under suitable calcination conditions. Fig. 3 shows the curves of TG/DTA analysis for the precursor after heat treatment at a heating rate of 10 °C/min, in which curve (a) for the microemulsion-derived zirconia precursor presents three major peaks: one for endotherm and the other two for exotherm. The endothermic peak at about 100 °C corresponded to the elimination of residual water and alcohols. The broad exothermic peak at about 303 °C on the DTA curve was probably due to the oxidation of organic and nitrate group residues. The latter peak at 490 °C, called the “glow exotherm”, was attributed to the crystallization of zirconia from amorphous and hydrous forms [9,16]. According to the results of the TGA analysis shown in curve (b) on Fig. 3, the weight dropped to 73 wt.%, and levelled off at 600 °C. Therefore, calcination temperatures used in this experiment were higher than 600 °C to burn out impurities completely.

3.3. Effect of HMDS treatment on particle size

The mean crystallite sizes of untreated and HMDS treated YSZ powder determined by the Debye–Scherrer equation are plotted in Fig. 4 by applying the XRD diffraction patterns. The crystallite size of the untreated powder, shown in curve (a), increased rapidly from 16 nm to 42 nm when the calcination temperature changed from 650 °C to 1100 °C.

In contrast to the untreated powder, the crystallite size of the HMDS treated powder was essentially maintained below 15 nm in the temperature range from 650 °C to 950 °C, as shown in curve (b). The measured BET (Brunauer–Emmett–Teller) specific surface areas were also consistent with the XRD observation. The specific surface areas of the untreated samples decreased rapidly from 84 m²/g to 29 m²/g in the temperature range of calcination between 550 °C and 850 °C. The BET results of HMDS treated YSZ powder dropped from 169 m²/g to 102 m²/g in the same temperature range. From the XRD and BET analysis, it is clear that the advantage of HMDS treatment is to prevent the YSZ nanocrystals from growing and thus maintain high surface area.

4. Conclusions

The yttria-stabilized zirconia precursors were prepared by the reverse microemulsion precipitation technique using a water/CTAB/hexanol system. The precursors were spherical in shape with a particle size range about 10–15 nm and were dispersed well in the surfactant matrix. The precursors were treated with hexamethyldisilazane (HMDS) so that the siloxyl groups grafted on the surface of YSZ precursors formed Zr–O–Si bonds after calcinations. The EPMA results showed that the amount of doped Si was about 1 mol%. The crystallite sizes of the HMDS-treated YSZ powder were kept smaller and rather uniform by adsorbing the siloxyl groups during calcination and thus the surface area remained high, when calcination was conducted below 1000 °C.
